Abstract

This study aims at mapping changes in landuse in the Lake Tanganyika micro-catchments in the Democratic Republic of Congo. It also aimed at assessing the level of pollution of L. Tanganyika resulting from offloaded material and nutrients from these rivers draining into the lake from the micro-catchments. Preliminary results showed that forest cover decreased significantly over time in favour of grasslands with scattered trees. The three micro-catchments loose considerable amount of sediments and nutrients annually. These unfortunately end up into the lake and may compromise the quality of its water and aquatic life therein. This therefore calls for establishment of means to maintain adequate forest cover in the micro-catchment, create awareness within communities in the micro-catchment about the risk of environmental degradation and its mitigation measures.

Key words:  Lake biodiversity, landuse, land degration, Uvira, water quality

Résumé

Background

The massive tropical forest in D.R. Congo, strategically located around the equator, has been considered for a long period as a local, regional and global climate regulator (Majaliwa, 1998). However, the country has undergone decades of instability and poor governance coupled with an exponential demographic pressure which could have trigged significant land use/cover and livelihood change with regional and global climatic impacts. In the Lake Tanganyika basin (LTB) the change in land-use/cover has accelerated land degradation which has negatively and significantly affected both water quantity and quality in the basin, and consequently peoples’ livelihood (Cohen et al., 1993; Alin et al., 1999).

Considering the importance of this forest ecosystem and the uniqueness of its resources, a quick restoration strategy is imperative. This requires the identification of hotspot areas and understanding their land-use/cover dynamics.

Literature Summary

For the last three decades the LTB has experienced high rate of land-use/cover changes compounded by climate change and variability. This has resulted into a wide range of effects, which have knock on consequences for food production, and therefore on human livelihoods around the lake (Pilsnier, 1999; Sarvala et al., 1999; Rüber et al., 1999; West et al., 2001; Verburg et al., 2003; Jørgensen et al., 2004). These changes have increased the sediments and nutrients fluxes into water bodies and increased the entropy of the open cycle poor management-degradation-poverty (Rogers, 1990; Ryan, 1991; Groombridge and Jenkins, 1998; Kerby and Kats, 1998; Runde and Hellenthal, 2000; Donohue and Irvine, 2003; Majaliwa et al., 2008). Assessing the impacts of these changes on the lakes is unfortunately complex because global warming may be making the lakes temporarily more oligotrophic while catchment changes increase nutrient and sediment flows to the lake. So responses to enrichment may be delayed more than the current oligotrophication trend (Reice and Wohlenberg, 1993).

Study Description

Three micro-basins of Lake Tanganyika in the territory of Uvira in eastern D.R.Congo were studied: Kavinvira, Mulongwe and...
Kalimabenge. The three rivers originate from the Mitumba Mountains (more than 2400 m above sea level for Mulongwe and Kalimabenge, and 1800 masl for Kavivira) and flow into Lake Tanganyika (779 masl). The D.R.C. catchment of the LTB covers about 40000 km²; representing about 20% of the basin. The climate is generally sub-humid with an average temperature of 25°C. The vegetation is dominantly woodland with scattered grasslands, and trees in cultivated lands. Landuse change in these catchment was assessed by comparing area under forest, secondary forest, cultivation, gourant, bare, built up and water bodies for the for the years 1974, 1986 and 2000. Landuse changes in the micro-catchment was mapped using landuse cover Modelar software. In addition, the flow, sediment load, total nitrogen and total phosphorus loads for the three different rivers in the Lake Tanganyika within Uvira city were determined.

Results

a) Land use change in the Mulongwe micro-catchment.
Land use change in Mulongwe micro-catchment is presented in Figure 1 and the summary presented in Table 1. From 1974 to 2000, the major land use/cover in the micro-catchment was grassland with scattered trees (50.10% in 1974, 60.49% in 1986 and 72.96 in 2000). Forest cover decreased significantly over
time in the micro-catchment area, while cultivated land appeared as a new land-use within the catchment in 1986 and built-up areas in 2000. All the other land uses remained almost intact. In 1986, the swamp disappeared in favour of settlement and grassland. By 2000, the grassland had increased by 12% and the cultivated land disappeared.

b) Sediment and nutrients loads into Lake Tanganyika.
Table 2 presents sediments and nutrient loads into Lake Tanganyika from the catchment, and is based on monthly measurements for a year. Kalimabenge has the highest flow and sediment load into Lake Tanganyika compared to Mulongwe and Kanvinvira. On the other hand, Mulongwe has the highest phosphorus and nitrogen loads.

There is need to:

- restore and maintain adequate forest cover in the selected micro-catchment, and thus reduce pollution of Lake Tanganyika.
- create awareness among all stakeholders including farmers, local leaders and policy makers on deforestation, the risk of
